PART I

INTRODUCTION

Historical Background

The first solar spectrum in the ultraviolet range that is inaccessible from the ground was obtained on October 10, 1946 by the Naval Research Laboratory (NRL) (Baum et al. 1946). Although the resolution was only 3\AA , this was sufficient to reveal many great absorption features: Si I 2882 \AA ; Mg I 2852 \AA ; Mg II 2803 \AA and 2796 \AA , the analogs of the H and K lines of Ca II; and numerous strong multiplets of Fe I and Fe II. During the next fifteen years there followed many observations of the solar spectrum from rockets, making use of far more powerful equipment. Within the range 3000 \AA to 2100 \AA , where the spectrum is almost exclusively one of Fraunhofer lines, an increase in spectral resolution by about one order of magnitude was achieved. Spectra having 0.5\AA resolution were obtained by both the Naval Research Laboratory and the University of Colorado. In the U.S.S.R. during 1956 and 1960 a group from the Institute of Optics in Leningrad flew a 1-meter grating spectrograph equipped with a solar pointing control (Jakovleva and Vedeshin 1978). With this instrument, spectra having 0.3\AA resolution from 2937 \AA to 2471 \AA were obtained on May 31, 1956; and in 1959, by using the same instrument in second order, a resolution of 0.15\AA was secured in the range 3100 \AA to 2700 \AA .

For the period through 1962, solar ultraviolet research from rockets has been described in detail by Tousey (1963). From these early flights came a series of publications best described as ultraviolet extensions of Rowland's Preliminary Table of Solar Spectrum Wavelengths (1895 to 1897) and of the Revision of Rowland's Preliminary Table by St. John et al. (1928). Mainly of historical importance are the first ultraviolet solar line lists of NRL (Durand, Oberly and Tousey 1949) and of the Applied Physics Laboratory of The Johns Hopkins University (Hopfield and Clearman 1948). The principal lists are the following: the spectra of NRL, from 2990 \AA to 2635 \AA by Wilson et al. (1954), and from 2635 \AA to 2085 \AA by Malitson et al. (1960); the spectra of the University of Colorado from 2965 \AA to 1800 \AA (Behring et al. 1958, McAllister 1960); and the spectra of the U.S.S.R. from 3100 \AA to 2635 \AA by Kachalov and Jakovleva (1962), and from 2635 \AA to 2471 \AA as a line list by Kachalov et al. (1958). Each of these publications except the last took the form of an atlas with the curve of spectral distribution plotted on a scale of absolute energy. The spectral resolution was in the range 0.15\AA to 1\AA . In the publications of NRL and of the University of

Colorado, the identifications of the lines were entered on the actual atlas curves. The identifications of the U.S.S.R. investigators were presented in the form of lists.

From the results of this first decade, it was already clear that an increase in spectral resolution by another order of magnitude would be necessary to resolve adequately the Fraunhofer lines in the ultraviolet solar spectrum. To achieve this required a spectrograph of small size and weight, yet capable of high spectral resolution. The timely development of the echelle diffraction grating by Harrison (1949), and of replication techniques by Bausch & Lomb, Inc. (Loewen 1972) under the direction of David Richardson, came at just the right time to make this possible.

In this report we present in final form a listing of the Fraunhofer lines as recorded by the NRL echelle spectrograph on the flights of 1961 and 1964. All plausible identifications have been made. In spite of much study many lines could not be identified, and so they will remain, awaiting further research in the laboratory.

For the first thirty years of space research, it was only the sun whose ultraviolet spectrum could be recorded with resolution sufficient to resolve satisfactorily the Fraunhofer lines. With the successful placing in orbit of an echelle spectrograph designed to study the stars (IUE 1978), there is available now a wealth of ultraviolet spectra of nonsolar objects. For the interpretation of these remarkable new spectra, this solar ledger will be of value.

The Echelle Spectrograph

Design of the NRL echelle spectrograph was commenced in 1952 by R. Tousey and F. S. Johnson. The instrument was completed by J. D. Purcell and flown on September 17, 1957. The peak altitude reached did not place the spectrograph above the entire ozone layer. Nevertheless the solar spectrum was photographed to 2600 \AA with a resolution of 0.1\AA , and the potential of the instrument was proved (Purcell, Boggess and Tousey 1958).

The second flight, August 29, 1961, was a complete success. The spectrum was recorded to 2200 \AA with a resolution of 0.03\AA , which was the best that was expected. In a third flight on November 21, 1964 the spectrum reached almost 2085 \AA , the end of the range typical of the photosphere; the resolution was 0.05\AA . The instrument and the spectra have been described in detail by Tousey, Purcell and Garrett (1967).

In order that the spectrograph be as compact as possible, it was constructed in the Littrow form with the echelle grating taking the place of the Littrow mirror. The echelle was of 73.25 grooves per mm, 2:1 ratio of groove width to groove height, and $63^\circ 26'$ blaze angle. The lens that provided both collimation and focusing was a triplet of 400 mm focal length with outer elements of lithium fluoride and central element of crystal quartz. Although the system was achromatized as completely as possible, there was a great deal of residual longitudinal chromatic aberration, which was corrected by pulling the film against a template of the proper shape. Separation of the many high-order spectra from the echelle was accomplished by cross-dispersion produced by a prism of calcium fluoride introduced between the lens and the echelle.

Because the intensity of the solar spectrum at $\lambda > 4000\text{\AA}$ is great by comparison with the rapidly decreasing intensity shortward of 3000\AA , it was necessary to minimize the radiation scattered by the echelle and the associated optical system. This was accomplished by means of a small, zero-dispersion double-monochromator constructed with Féry prisms of quartz. This predisperser was placed directly before the slit. The entire instrument was kept pointed at the sun with a solar pointing control that corrected for the yaw and pitch of the rocket.

Although the predisperser was adjusted to reject the entire solar spectrum at $\lambda > 3300\text{\AA}$, the residual scattered light was not negligible and set a limit on the shortest wavelengths that could be photographed. On the 1961 flight the spectrum reached 2200\AA before it became swamped with stray light. For the 1964 flight the predisperser was readjusted to reject all radiation of $\lambda > 2500\text{\AA}$. As a result, the stray light was reduced and the spectrum extended nearly to 2085\AA .

A second effect of the scattered light was to fill in somewhat the bottoms of the strongest Fraunhofer lines. Contributing to this was another type of stray light produced by ghosts present in the echelle images. To evaluate this "nearby" stray light, the spectrum of a source containing narrow emission lines was photographed in the laboratory. The profile of Fe II 2739.545 \AA from line-center to 10% of peak was found to be approximately Gaussian with a full width at half maximum (FWHM) of 0.03\AA . Farther from line-center it broadened faster than Gaussian and beyond 0.1\AA from line center the intensity remained at about 1% of peak. It is difficult to evaluate precisely the magnitude of these effects. Although the stray light increased in intensity with decreasing wavelength, the increase was not sufficiently rapid to affect relative intensities within multiplets. It is not certain that any faint lines were obliterated by scattered light except at the short-wavelength end of the spectrum.

The optical characteristics of the system were such that radiation was accepted from the sun's center to about $1/3 R$. Therefore, the echelle spectra should be regarded as disc spectra with no significant contribution from regions near the limb.

The Echelle Spectra

The solar spectrum photographed by the echelle spectrograph on the flight of 1961 is reproduced in Fig. 1. In actual size the frame measured $25\text{mm} \times 25\text{mm}$. To record photographically the entire spectral range required exposures of several different times, and Fig. 1 is a composite. The dispersion on the film runs linearly with order number, shown at the left, from 2.5\AA/mm near 4000\AA to 1.25\AA/mm at 2000\AA . For wavelengths greater than 3069\AA the spectrum was not studied because this region is well known from the ground-based observations (Moore, Minnaert, Houtgast 1966).

For the shortest wavelengths the most useful spectra were obtained from the flight of 1964, as shown in Fig. 2. Although the spectra extend to 2085\AA , approximately, the lines reported here are limited to $\lambda > 2095\text{\AA}$. Below 2085\AA the continuum intensity falls by a factor of 4 or 5 within 15\AA . Therefore, shortward of 2085\AA the Fraunhofer lines are almost vanishingly faint and little of value was present in the spectra below 2095\AA .

The spectral resolution in the 1961 spectra was 0.03\AA . This was consistent with the 0.03\AA FWHM of Fe II 2739.545 \AA , determined in the laboratory before flight. In the 1964 spectra the resolution was 0.05\AA , owing to a slight deterioration of adjustment during flight. Twelve exposures were made during each flight, of times between 2 s and nearly 100 s.

The Preliminary Solar Ledger

Analysis of the echelle spectra was commenced soon after the 1961 flight. The first task was to establish a wavelength scale. This could not be done with sufficient precision simply by using the grating equation because of the great distortion introduced by the several refractive elements in the optical system. It was necessary also to establish a separate wavelength scale for each order. This was done empirically by comparison with exposures made with a low-pressure, RF-excited iron arc which produced a rich, narrow-line spectrum of Fe I and Fe II. The iron lines were used as internal standards for the generation of the dispersion curve for each order. The dispersion equation was set up as a third order polynomial with coefficients adjusted by computer until the residuals were minimal and random. With the aid of these dispersion equations the wavelengths of the solar lines were derived for each order from their measured positions.

The first solar ledger was prepared from the 1961 spectra by L. E. Giddings. The list extended from 3069\AA in order 80 to 2288\AA in order 106. By making use of the 1964 spectra, the list was carried to 2095\AA in order 116. The complete list contained 7146 lines. The lines in this preliminary ledger were identified as to chemical origin by P. A. Simmons. The identifications

were based mostly on the Multiplet Tables (UV and MT in the references). Identifications were proposed for about half of the observed solar lines. Although considered preliminary, copies of the ledger were distributed on request.

The NRL Solar Atlas: 2226Å to 2992Å

The preparation of an atlas that would contain curves of spectral irradiance at one AU in absolute units of energy and at full spectral resolution was commenced soon after the 1961 flight. The best spectra were scanned with a microphotometer and the values of density were converted to relative intensities by means of photographic characteristic curves. Finally, the relative values of intensity were converted to absolute values of irradiance in $\mu\text{Wcm}^{-2}\text{\AA}^{-1}$. This was done by adjustment of the relative

intensity curves to the curves of absolute intensity at 2.5Å spectral resolution of Wilson et al. (1954) and Malitson et al. (1960). The adjustment was carried out at 142 wavelength positions scattered over the entire range. The curves of lower resolution had been calibrated by comparison with data from an instrument designed primarily for the measurement of the absolute spectral solar flux. This procedure was complex and is described in detail in the NRL Atlas (Tousey et al. 1974).

The wavelength scale for the Atlas was derived from the Preliminary Ledger, which was nearing completion well before the Atlas was completed. The short-wavelength end of the Atlas coincided with the end of the echelle spectrum of 1961. The long-wavelength end was set somewhat arbitrarily by the end of order number 80, and because the Atlas being produced from observations at the Jungfraujoch Observatory was expected to extend to 3000Å (Delbouille, Neven and Roland 1963, 1973).

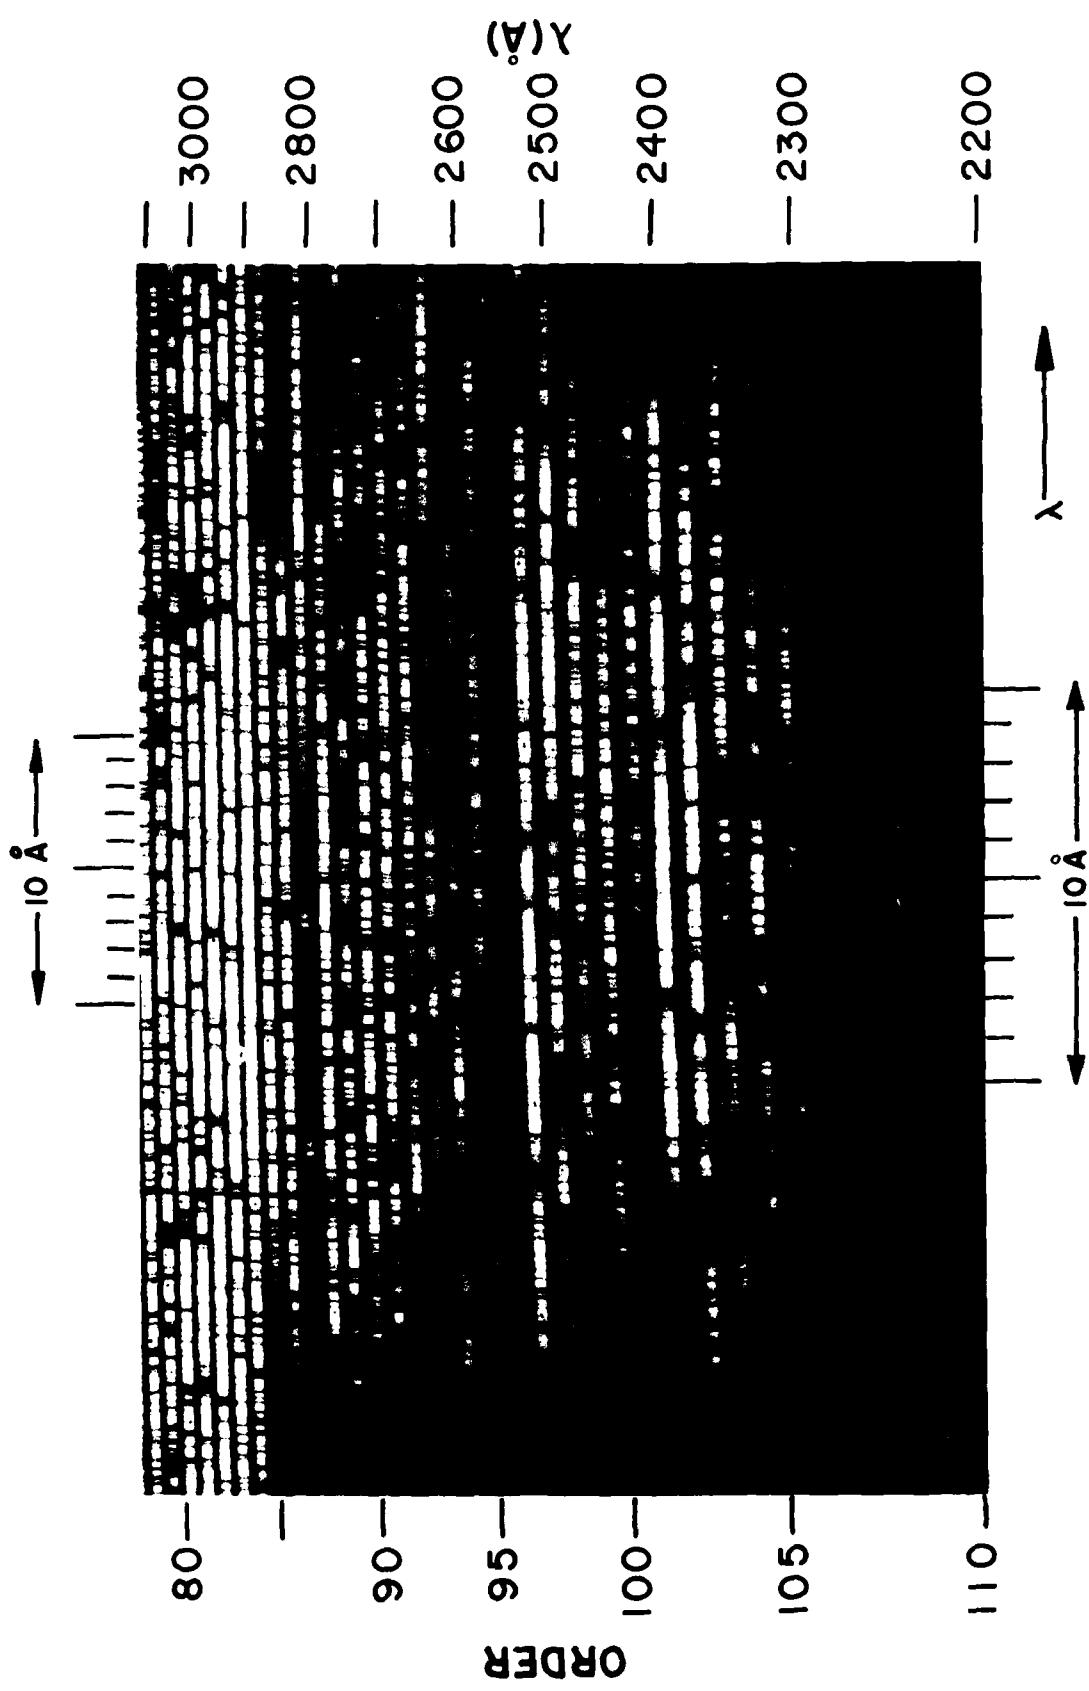

Fig. 1 — The Ultraviolet Solar Spectrum recorded on August 29, 1961 with the NRI Echelle Spectrograph

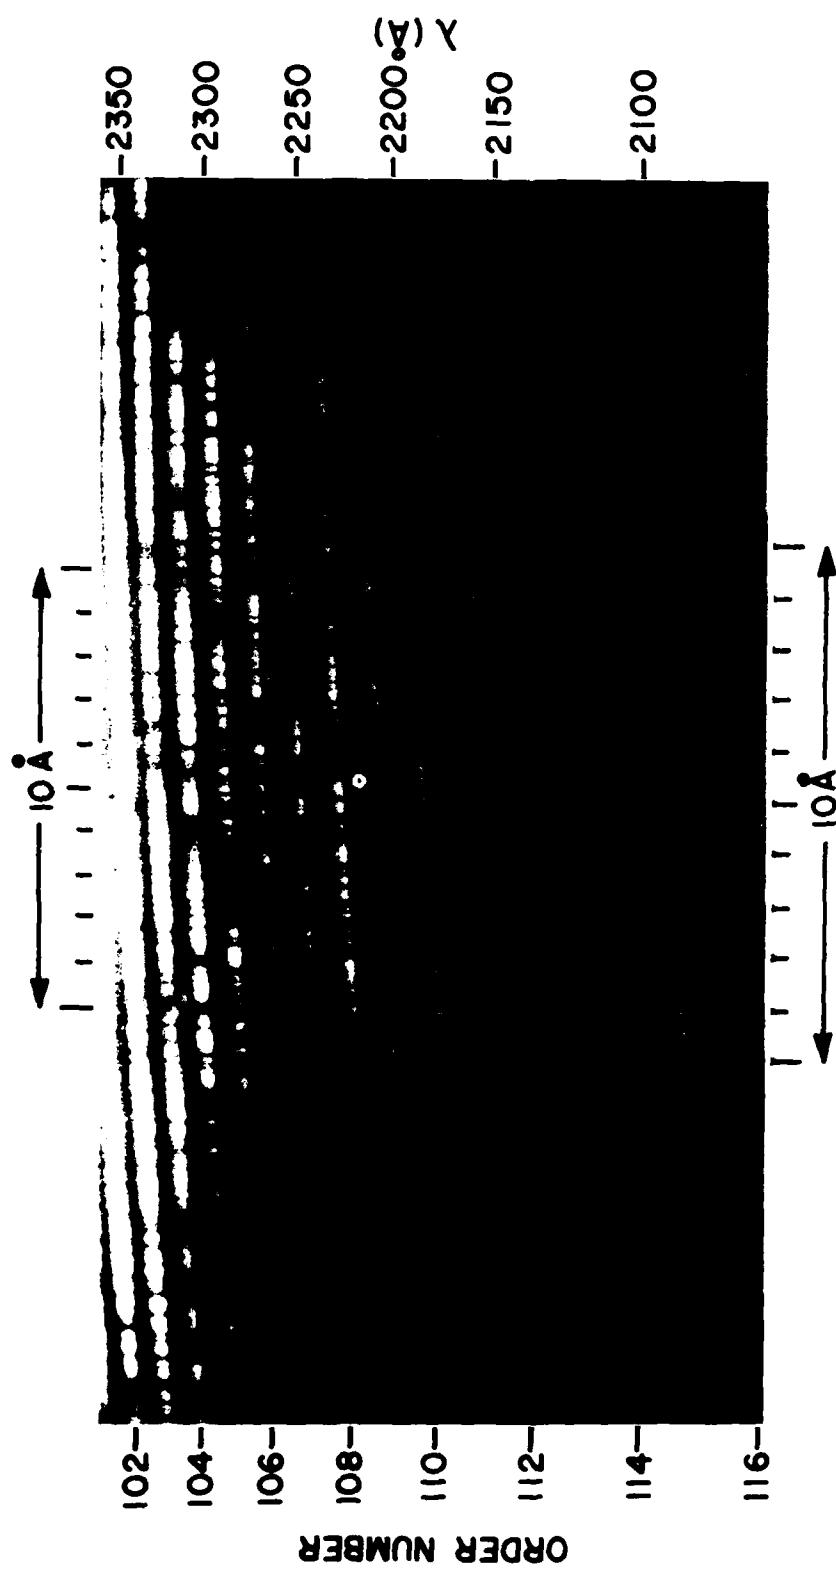

Fig. 2 — The shortest wavelengths in the solar spectrum recorded on November 12, 1964 with the NRI Echelle Spectrograph

PART II

THE FINAL SOLAR LEDGER

Procedure

In preparing the Final Solar Ledger the Preliminary Ledger has been extensively revised. The wavelength and intensity of each solar line were reconsidered. New lines were added and doubtful lines were deleted. The identifications were restudied in detail, taking into account laboratory wavelengths published or available through mid-1981. The complete multiplet structure was examined for each multiplet believed to be present or expected. Lines of individual spectra were identified on the basis of the behaviour of their ultimate lines including those outside the NRL echelle range.

The reexamination of the spectra involved a study of the same set of prints that formed the basis for the preliminary list. One print was available for each order, taken from the exposure of most suitable density. These prints were enlarged to a dispersion of about 1 Ångstrom per inch; therefore, all lines could be studied easily without using a magnifier. Also taken into consideration was the Atlas, which was not available when the preliminary list was compiled. The Atlas often served to disentangle features that were not clearly interpretable from the prints.

The Final Solar Ledger is based on the NRL echelle spectra only. Other spectra obtained since 1964 are discussed in Part IV. The spectroscopic material used for identification includes the Multiplet Tables of Moore (1945-1981), supplemented by data published after completion of the various Multiplet Tables and by unpublished work available to mid-1981. Predicted wavelengths have been used where laboratory measurements are missing for members of multiplets expected to be present in the solar spectrum.

The preparation of the Final Solar Ledger from the Preliminary Ledger proceeded as follows. First, the identifications were examined in detail as described above, by element and ion from the lightest atom through the heaviest that might possibly be encountered. From all available material, the best laboratory wavelength was chosen for each line and a judgment was made of its value for use as an internal standard of wavelength. Then, by reexamining the prints, the reality of each line was verified and its wavelength was checked by interpolation between the various nearby lines that appeared to be suitable as standards. At the same time

visual intensities were reexamined and compared with the intensities expected from laboratory data, and also with the intensities in the Atlas. It was always necessary to consider blending and masking and to estimate the expected intensities of contributors by consideration of the intensities of related well-identified unblended lines.

The result of this iterative process is the Final Ledger that forms the main body of this publication. In character this final solar line list is conservative; many lines in the preliminary list have been omitted, a smaller number have been added.

The Solar Wavelengths

In column 1 of the Solar Ledger the wavelengths in air and in Ångstrom units are listed for all features present in the echelle spectra. All entries refer to ordinary, unblended lines of width consistent with the instrumental profile, 0.03Å FWHM, unless accompanied by a brace. A brace in Column 1 indicates a pair or group of lines between the tabulated wavelength-limits that are not completely resolved but for which it was possible to assign separate wavelengths and intensities. A brace in the intensity column indicates that two or more lines are present but not well-resolved, and that a single intensity has been given to the entire feature.

The process of determining wavelengths was one of continual adjustment and fitting. Beginning at one end of an order, a print was examined and the identified lines were noted together with their laboratory wavelengths and intensities. Although the dispersion was not constant along an order, within intervals of one or two Ångstroms it was sufficiently constant to permit making a linear interpolation. For each short interval a linear scale was constructed, based on solar lines believed to be unblended and satisfactory for use as internal standards. Wavelengths of unidentified lines were read from these scales. Wavelengths of identified lines not used as internal standards were also checked. Inevitably, the wavelengths of some such lines were not in acceptable agreement with the laboratory values. In each such case a decision was made as to whether the line was incorrectly identified or whether it was a blend.

All solar wavelengths are given to two decimal places even though it has been stated in earlier publications that the accuracy is better than 0.01Å. In general,

the probable error of each solar wavelength is considered to be about $\pm 0.005\text{\AA}$. In selected regions three-place entries may be justified for lines of good quality that show no effects of blending, provided that there are satisfactory lines nearby for use as standards. At the short-wavelength end the error is larger, and at 2095\AA the Ledger was terminated.

The Solar Intensities

The estimated intensities of the solar lines are given in column 2 on a scale that was strictly visual. The scale was arbitrary, from 1 for the faintest lines to 9 for the strongest. Features that were too broad to be single, narrow lines were indicated by the following symbols in Column 2, which are descriptive of the character of the line:

<i>D</i>	wide and double (unresolved pair)
<i>d</i>	double
<i>H</i>	very hazy
<i>h</i>	hazy
<i>W</i>	very wide
<i>w</i>	wide

Values of visual intensity were assigned to lines by studying the appearance of images on the large prints. A comparison was also made with the intensity tracings in the Atlas, taking particular note of the depths of the lines. In this way it was possible to set up a range of central intensity for each value of visual intensity. This process of comparison was particularly helpful for assigning meaningful visual intensities at the ends of orders where the contrast was less, and for making certain that the scale of visual intensities carried over from order to order.

Visual intensities have their greatest significance, of course, over short ranges of the spectrum, and lose meaning rapidly the greater the wavelength difference between the lines being compared. This is especially true of the echelle spectrum, whose character changes greatly as the short wavelength end is approached. Over the wavelength-range of most multiplets, however, the visual intensities assigned to the solar lines can be compared directly with the relative intensities reported for laboratory spectra.

Broad, strong lines with extended wings presented two difficulties when assigning visual intensities. The prime examples of such lines are Mg II 2796\AA and 2803\AA , each of which dominates the spectrum over some 30\AA , and Mg I 2852\AA which spans more than 15\AA . To a lesser degree the same is true of the leading lines of Fe I, Fe II, Ni I, Mn II and Si I. The first difficulty was in the assignment of a visual intensity that would take into account both the central depth and the width for a very broad, intense line. Arbitrarily, intensities 8 and 9 were restricted to lines that are wide as well as deep. For the

Mg lines noted above, however, a meaningful assignment of intensity could not be made.

The second difficulty related to the obscuring effect of a very wide line on other lines that lie within the span of its wings. Rather than base the visual intensity strictly on conspicuously for a line lying within a broad wing, an allowance was made for the effect of the wing on its apparent strength. This was an imprecise procedure at best, and it is probable that the intensities were underestimated for lines lying in the deepest parts of strong, wide lines.

A list of lines judged to be "winged" is presented in Table 1. They were selected by examining systematically their profiles as shown in the Atlas. The criterion for inclusion was appearance, independent of origin or multiplet structure. Columns 1 to 4, wavelength, intensity, identification, and multiplet number, were taken from the Ledger. The fifth column lists the low excitation potential as given in the multiplet tables. The last column gives the effective span of the wings in λ , and $\Delta\lambda$. This span, estimated arbitrarily to an accuracy of about 0.1\AA , although far from well-defined, serves as a guide to the possible masking effect of the wings. Of the 90 winged lines listed in Table 1, 76 are single lines, 12 are blends of two lines, and 2 are blends of three lines, for a total of 106 lines. Most of these lines are of intensity 6 or greater and in the Ledger are described as "*W*", as would be expected.

The Identification of the Solar Lines

The spectra identified as accounting for the observed solar lines are entered in the Final Solar Ledger as columns 3 to 6: atomic or ionic spectrum; multiplet number; laboratory wavelength, accompanied by the symbol \dagger in the case of a raike ultime; and reference, respectively. Two molecular spectra are included: OH, known to be present and strong at longer wavelengths; and SiO, which is identified here for the first time. Where the solar feature is produced by more than one line the contributors are entered in order of increasing wavelength.

The symbols in column 3 have the following meanings:

- following the identification denotes that the laboratory line is to the violet of the solar line, and vice versa for the dash preceding.
- || preceding the identification indicates a predominant contributor, which almost but not completely masks all other contributors.
- | preceding the identification denotes a principal contributor which is only moderately the strongest contributor to a blend.

Table I — Winged Lines in the Echelle Solar Spectrum

Solar Wavelength Å	Intensity	Identification	Multiplet No.	Low E P	Span of Wings Å

*Entered in Ledger as a blend, but in the study of the winged lines the predominant contributor was considered as unblended

For example,

2166.19	5D	Ni I— Fe II
---------	----	-------------------

2165.55	6d	Ni II Fe II
---------	----	----------------

The solar intensity to be expected, as judged by the intensities of other lines in a multiplet, has been the guiding factor in deciding the question of principal vs. predominant contributor.

Multiplet numbers (column 4) are taken from three sources:

- The Ultraviolet Multiplet Table
- The Multiplet Table of Astrophysical Interest
- Selected Tables of Atomic Spectra

The Multiplet Tables are noted in column 6 as UV and MT, respectively. Multiplet numbers from the MT are bracketed throughout to distinguish them from those in the UV Tables.

The laboratory wavelengths used to identify the solar lines as to chemical origin are recorded in column 5. Many of these values are taken from the Multiplet Tables, but additional values have been quoted from revised and extended analyses, or from more homogeneous lists of wavelengths. Certain solar identifications have been based on predicted wavelengths in cases where expected members of multiplets have never been observed in the laboratory. In these cases the appropriate multiplet numbers are entered in column 4. No multiplet numbers have been added, however, for new multiplets that are known from revised analyses of various spectra. For cases of laboratory blends, where one line has more than one designation, both multiplet numbers are given in column 4 and the wavelength is repeated in column 5. For example,

2399.25	8W	Fe II	2	2399.237
		Fe II	36	2399.237

For molecular lines the chemical symbol is entered in column 3; in column 4, instead of a multiplet number the vibrational quantum numbers are given, enclosed in parentheses.

Reference numbers for the identification work are in the last column. This reference list follows the Ledger.

The first column in the reference list indicates the spectra for which each reference has been used.

Criteria for the Identifications

One criterion for reliable identifications is satisfactory agreement between solar and laboratory wavelengths. For prominent solar lines there was rarely any question when the wavelength agreement was good and the particular spectrum was known to be well represented in the solar ledger. Throughout the identification work, however, multiplet structure was considered in detail together with wavelength agreement. The general run of solar intensities within multiplets was an important guide and blended lines were often detected from intensity anomalies. Lines that were expected but missing had to be accounted for. Masking of lines falling within the wing-span of the strongest solar lines has required extensive detailed study throughout the work.

The degree of agreement expected between solar and laboratory wavelengths varies greatly depending on the width and general character of the solar line. In addition, the accuracy of laboratory wavelengths varies widely among different spectra. For a line that appeared to be unblended, a tolerance of $\pm 0.03\text{\AA}$ (Sun - Lab) was taken as acceptable in most cases. For a few partially resolved blends, winged lines, or other complex features a greater tolerance was allowed.

The winged lines of Table 1 and many other strong lines often masked lines that should have been present on multiplet evidence. The decision whether to include a missing line in the ledger as a contributor to a blend, or omit it as masked was often difficult and always involved personal judgment.

A complete list of lines believed to be masked was prepared but is too long to include. A selected list of the more important masked lines is given in Table 2. The arrangement is by increasing atomic number, Z (column 1), followed by the spectrum (column 2), and by the laboratory wavelength, intensity, and multiplet number of the line believed to be masked, (columns 3, 4 and 5). The wavelength and visual intensity of the solar masking line are given in columns 6 and 7; the identification and multiplet number of the masking line are in the two columns that follow. The entries for the masking lines, (columns 6 to 9), are taken from the Solar Ledger. The last column, (Sun - Lab), gives the wavelength separation between the masking line and the missing line.

PART III

GENERAL DISCUSSION

By the time of the commencement of World War II a great deal had already been learned about the chemical composition and the physical structure of the sun from diligent work on its "accessible" spectrum. The first evidence that short-wavelength emissions must exist came from the need to explain the earth's ionosphere. Proof that extreme ultraviolet radiation is emitted from the sun came soon after 1940 from the identification of the long-unexplained coronal lines in the visible (Grotrian 1939 and Edlén 1942). The green coronal line 5303 Å, for example, was produced by a forbidden transition in Fe XIV whose excitation required the emission of lines in the extreme ultraviolet near 265 Å.

The success in 1946 in obtaining observations from a V-2 rocket of the ultraviolet solar spectrum, pointed the way toward eventually observing the entire spectrum of the sun, a long-cherished dream of astronomers. New interest in the observation of the sun was immediately generated. Following the first twenty years of research based on rocket spectra, a general summary of the situation just prior to the availability of the echelle spectra was given in the 1966 Solar Monograph (Moore, Minnaert, Houtgast).

Summary of Spectra Identified

The raias ultimes of twenty-nine spectra lie within the range covered by the echelle spectrograph (Table 3). These raias ultimes include 11 first spectra, 16 second spectra, and 2 third spectra. They are the lines of these spectra that one would expect to be the strongest in the sun.

Twenty-three of the raias ultimes are present in the solar spectrum, four are masked, and two are absent. Those that are present are indicated by the symbol + following the wavelength in column 5 of the Ledger.

A summary of the spectra identified in the Ledger is presented in Table 4, which includes 34 first spectra, 29 second spectra, 2 third spectra, and 2 molecular spectra. Columns 1 and 2 of Table 4 contain the atomic number and the spectrum, with molecular spectra entered at the end. Columns 3 and 4 give the approximate numbers of unblended and blended solar lines ascribed to each spec-

trum. Column 5 indicates the solar intensity of the strongest unblended line, with Mg I and Mg II omitted for reasons that are obvious.

Some Identifications of Special Interest

Hg I: In the 1966 Solar Monograph,⁴² Table 13 contained a summary of "Chemical Elements in the Sun," and stated that "Further study of Hg I is needed." On the basis of the present work Hg can now be considered present in the sun. See details below.

C II: Although the spectra of carbon through C VI are now familiar features in extreme ultraviolet solar spectra, when progressing from the visible to shorter wavelengths the first accessible lines of C II occur in the echelle range.

Cu II and Cd II: These spectra are observed in the sun for the first time from the presence of their raias ultimes.

Pt II: This spectrum is listed as present from the echelle data.

Yt III and Gd III: These third spectra appear in the list of newly identified spectra. For Yt III the evidence is provided by the riae ultime.

B I, Tc II, Ce III, Tb II and Th II: The leading lines of these spectra fall within the echelle range and might be expected to be present. They are absent or masked. Special discussions of these spectra follow in the section "Comments on Spectra Absent from the Echelle Ledger."

Li I: The riae ultime, 6707.761 Å,²⁰ is strong in the spot spectrum but is absent from the disk spectrum because of the low ionization potential of Li I. The second series member, 3232.634 Å, is absent. The third member, 2741.186 Å, agrees with a solar line observed at 2741.21 Å, but this is considered to be a chance coincidence.

Tm III: The strongest line observed in the laboratory, 2489.437 Å,⁵⁴ is absent.

OH and SiO: Molecular spectra of OH and SiO have been identified in the echelle range and are described in the section on "Molecular Spectra." OH lines are familiar and numerous, but SiO is reported here for the first time.

Pending further observations, no identifications of the NH band at 3050 Å have been entered in the Ledger.

Table 3 — Raies Ultimes

Notes on Selected Spectra

Z = 12; Mg I: The strength of the raike ultime, 2852.127 Å, is enormous. Other series are well represented. The series $3p\ ^3P^o - ns\ ^3S$ is present from $n = 6$ to 13; for $n = 14$ to 21 the wavelengths are predicted. The series $3p\ ^3P^o - nd\ ^3D$ is present from $n = 5$ to 18 and may run to $n = 22$; wavelengths from $n = 14$ are predicted.

Mg II: The analogs of H and K of Ca II, 2795.528 Å and 2802.704 Å, are the dominant features of the entire echelle range. Three series have been

extended to the ultraviolet and identified from predicted wavelengths:

$$4s\ ^2S - np\ ^2P^o \quad (n = 6, 7)$$

$$3d\ ^2D - nf\ ^2F^o \quad (n = 10)$$

$$4p\ ^2P^o - ns\ ^2S \quad (n = 10, 11).$$

Z = 13; Al II: The series limits associated with the ground term $3p\ ^2P^o$ lie at 2070.626 Å and 2075.443 Å. Absorption in the several series converging to these limits and beyond accounts for most of the great decrease in

Table 4 — Summary of Spectra in the Echelle Ledger: Counts of Lines

Note 1 See Table 3, Raies Ultimes

Note 2 See "Notes on Selected Spectra" below

intensity of the solar continuum short of 2100Å. Many lines in these series are present, mostly from two series:

$$3p\ ^2P^o - ns\ ^2S \quad (n = 5 \text{ to } 17); \quad n = 17 \text{ predicted}$$

$$3p\ ^2P^o - nd\ ^2D \quad (n = 4 \text{ to } 16).$$

Al II: In multiplet 1, 2669.157Å is unblended; in multiplet 14 only the strongest member, 2637.689Å, is present and is faint. The singlet line, 2816.185Å multiplet 7, is probably blended with the riae ultime of Mo II, 2816.153Å.

Z = 14; Si I: Nearly 50 lines are present and many are strong. (see Table 5). A paper on "The Presence of Si I series in the Ultraviolet Solar Spectrum 3000Å to 1200Å" was published in 1977.⁴¹

Si II: The 4 identified lines are from multiplets 0.01 and 17.

Z = 15; Pt I: This spectrum was first identified in the sun from lines of $\lambda > 9100\text{\AA}$ (Moore, Babcock and Kiess 1934). This earlier work is well confirmed by the presence of some 20 low-level lines in the echelle range.

Z = 20; Ca I: The series $4s^2\ ^1S - 4s\ np\ ^1P^o$, of which 4226.727Å is the leading member, extends from $n = 5$ to 9.

Ca II: The identifications are based on predicted wavelengths, all believed to be reliable.

Z = 21; Sc I: Multiplets [10] and [11] are faintly present. The one unblended line is 3014.364Å.

Sc II: Three leading lines of multiplet 1 are unblended. The remaining lines are from multiplets 2 and [37].

Z = 22; Ti I: The strongest multiplets, 1, 2, and 5, are well represented, and contain only a few blends.

Z = 25; Mn I: The strongest lines are from multiplet 1 and are unblended.

Z = 26; Fe I: The ultimate lines of Fe I are among the strongest Fraunhofer lines (see Table 5). Almost every known line of Fe I is present in the spectrum of the solar disk and many as yet unidentified lines are probably lines of Fe I.

The most extensive line list of Fe I is found in the paper "Iron-Neon Hollow Cathode Spectrum" by H. M. Crosswhite.⁷ In addition C. M. Brown and associates¹ have observed Fe I in absorption from 2142Å to 1550Å; more than 60 of these lines have been identified in the echelle spectrum. About 70 unclassified lines of Fe I from the early Princeton line list⁵¹ have also been identified.

Use was made of two extensive lists of predicted Fe I lines that have not been published⁴³: a list by J. L.

Tech, based on "Atomic Energy Levels" and 12 miscellaneous levels,²⁹ and a similar list by C. M. Brown, which includes recent work by U. Litzén.³¹ More than 200 of these predicted lines have been identified in the echelle spectrum.

Fe II: A revised and extended analysis of Fe II by S. Johannson²³ was used extensively. In addition, wavelengths predicted from Johannson's term values provided identifications of more than 30 unidentified solar lines. The most important predicted lines are found in multiplets 4 and 32.

Z = 28; Ni I: The strongest lines are from multiplet 24. The following unclassified lines have been identified from UV, Ref A:

Laboratory Wavelength	Laboratory Int.	Laboratory Wavelength	Laboratory Int.	Laboratory Wavelength	Laboratory Int.
2277.767	6	2313.649	5	2703.615	2
2308.168	4	2322.683	5	2903.653	1
2309.484	4	2346.074	3	2932.618	4
2310.016	3	2559.655	6		

A few Ni I lines have been identified from predicted wavelengths.³⁸ The level values in Ref. 48 have been used.

Z = 29; Cu I: Only the strongest lines from the two lowest terms are present.

Cu II: The presence of the riae ultime provides the first evidence of Cu II in the solar spectrum. This spectrum has excellent "Reference Wavelengths".²⁵

Z = 31; Ga I: Three lines from multiplet 1 and one from multiplet 3 appear to be unblended.

Z = 32; Ge I: The leading lines, multiplets 1 and 2, are present and unblended. A few lines from the second lowest term are also present. All of the Ge I lines are in the list of "Reference Wavelengths".²⁵

Z = 33; As I: The presence of As I in the sun was reported in 1976.³⁹ The riae ultime, 1890.42Å, was identified by C. M. Brown in a rocket spectrogram and all three members of multiplet 1 appear to be present. On the basis of this evidence two lines near 2300Å in the echelle spectrum have been attributed to the leading lines of As I, multiplet 6.

Z = 38; Sr I: Five members of the series $5s^2\ ^1S - np\ ^1P^o$ ($n = 6$ to 11) appear to be present but faint; one is masked.

Sr II: The two leading lines of multiplet 3 near 2160Å appear to be present but faint.

Z = 39; Yt II: The two leading lines of multiplets 1 and 2 are accessible and present.

Yt III: The leading lines of multiplet 3 are 2817.037 \AA and 2946.014 \AA . The solar line 2817.04 \AA is identified as Yt III and provides the first evidence of the presence of this spectrum. The second line is absent.

Z = 41; Nb II: The identified lines are from multiplets 9, 14 and 15. The riae ultime, 3094.172 \AA , is outside the present range.

Z = 42; Mo I: Only the strongest accessible line, 2225.437 \AA multiplet 2, is present; it is faint and hazy.

Mo II: Six lines of multiplet 4 are present but faint; three are blended.

Z = 44; Ru I: The leading line of multiplet 1, 2874.984 \AA , may contribute to a solar line of intensity 3 due mostly to Cr II.

Ru II: Five lines of multiplet 41 and the strongest line of multiplet 42 are the only lines entered as present.

Z = 48; Cd I: In the 1966 Solar Monograph⁴² the low-level intersystem line of Cd I, 3261.050 \AA , was listed as present. The presence of the riae ultime as an unblended line in the echelle spectrum confirms the earlier work.

Cd II: The riae ultime is the violet component of a close pair of lines. The second member of multiplet 1 is masked. No other lines of Cd II have been observed in the solar spectrum.

Z = 50; Sn I: A faint solar line at 2863.30 \AA , is identified as Sn I (multiplet 1).

Z = 51; Sb I: The two accessible lines in multiplet 1 are present but faint.

Z = 56; Ba II: Multiplet 2 is present. The second and third lines are unblended. The strongest line, 2335.269 \AA , probably contributes to the double solar line 2335.21 \AA , intensity 5d, which is unidentified. The wavelength discrepancy is unexplained; therefore the Ba II line is listed in Table 2 as masked.

Z = 64; Gd III: The two leading lines, 2955.534 \AA , and 2904.726 \AA , appear to be present, but faint. This is the first identification of Gd III in the solar spectrum.

Z = 71; Lu II: The presence of the riae ultime as the principal contributor to a solar blend confirms the presence of three lines attributed to Lu II in the 1966 Solar Monograph.⁴²

Z = 74; W I: The strongest accessible line, 2946.989 \AA , is very faint in the echelle spectrum. The presence of the second line, 2818.060 \AA , is dubious.

Z = 76; Os I: The riae ultime is masked. A weaker but strongly reversed line, 2838.626 \AA , multiplet 12, appears to be present but faint.

Z = 77; Ir I: The identification of Ir I at $\lambda > 3000\text{\AA}$ is confirmed by the presence of three reversed laboratory lines in the present range. The riae ultime is masked.

Z = 78; Pt II: The first and only evidence of Pt II in the solar spectrum is from 2144.244 \AA , which is observed in the laboratory as a blend of Pt I and Pt II.

Z = 79; Au I: In the 1966 Solar Monograph⁴² one line, 3122.784 \AA , is identified as Au I; this was the only evidence of gold in the sun. In the echelle range the presence of 10 lines confirms the earlier assignment. Blending is troublesome, but the strong line 2352.58 \AA , multiplet 5, is unblended. The riae ultime is blended with Mn II.

Z = 80; Hg I: The familiar intersystem line, 2536.517 \AA , multiplet 1, is present in the echelle spectrum. The correctness of this identification is supported by the riae ultime, 1849.492 \AA , multiplet 2, found present in absorption in a rocket spectrogram photographed by NRL. This solar line was measured at 1849.50 \AA and identified by C. M. Brown. These two solar lines are the first and only lines attributed to Hg I.

Z = 82; Pb I: The strong line, 2833.060 \AA , multiplet 1, may contribute to a solar line due partly to Fe II. The first line in multiplet 2 is masked by Mg II.

Comments on Spectra Absent from the Echelle Ledger

Z = 5; Bi I: The search for Bi I in the solar spectrum has been unrewarding,³⁹ and this holds true for the echelle spectrum as well. The leading lines, 2497.7233 \AA and 2496.7717 \AA ¹¹ are masked. The solar line in the present ledger at 2496.77 \AA is attributed to an unclassified line⁷ of Fe, 2496.792 \AA , rather than to Bi I. The analysis by Kchl et al. (1977) of the Harvard-Smithsonian spectrum for Bi I does not take into consideration this line of Fe.

Z = 43; Tc II: The possible presence of technetium in the sun was noted in 1951 on the basis of leading lines of Tc II longer than 3000 \AA , but the evidence was inconclusive.³⁶ The riae ultime, 2543.227 \AA , multiplet 1, is absent from the echelle spectrum. The second line in the multiplet, 2609.993 \AA , coincides with a line of Fe ascribed to the faint solar line 2610.00 \AA . The third member of the multiplet is absent.

As was stated³⁶ in 1951, the identification depends upon the existence in nature of an isotope having a half-

life "of the order of 4×10^8 years or more." More recently, Cahn and Glashow (1981) state that the most stable isotope has a half-life of only 4.2×10^6 years. Therefore, no definitive statement regarding the presence of Tc is justified.

$Z = 58$; Ce III: This spectrum deserves special mention. The rare ultime, 3055.589\AA ⁵³ is masked in the echelle spectrum. In the 1966 Solar Monograph⁴² a faint Rowland line at 3055.594\AA is identified as "Ce III?", the only third spectrum included.

$Z = 65$; Tb II: E. Meinders³⁴ reports 32 strong, classified lines in the echelle range. Of these, only 2 might be present unblended: 2897.444\AA and 2914.755\AA , having respective solar intensities 1 and 2. This evidence is so dubious that no solar lines have been attributed to Tb II. The presence of Tb II in the sun still remains questionable, as stated in 1966.⁴²

$Z = 90$; Th II: The rare ultime, 4019.129\AA , provides the only evidence of the presence of a radioactive element in the solar spectrum. The next strongest line, 2837.295\AA ⁵⁹, is masked by Fe II in the present ledger.

Molecular Spectra

OH: the leading bands of the $A^2\Sigma^+ - X^2\Pi$ system, (0-0), (1-1), and (2-2), are strongly represented in the solar spectrum at $\lambda > 3000\text{\AA}$.⁴⁰ They account for 175 unblended solar lines and contribute to 124 blends. In the above reference it is noted that the (1-0) and (2-1) bands should be present and "may be detected when high-dispersion rocket spectra become available." In fact, the (1-0), (2-1), (0-0), and (3-2) bands fall in the echelle region and are present, the (1-0) band being the strongest with the leading lines, 2833.843\AA and 2835.530\AA , each having solar intensity 5.

Approximate counts of the identified OH lines are as follows:

OH $A^2\Sigma^+ - X^2\Pi$

Band	Unblended	Blended	Total
0-0	10	3	13
1-0	56	46	102
2-1	14	20	34
3-2	7	6	13
Total	87	75	162

SiO: The $A^1\Pi - X^1\Sigma^+$ system is judged to be present in the echelle spectrum. Some 70 lines are entered in the ledger; about 40% are blends. The evidence comes from (0-1), (1-0), and (2-0) bands.

The strongest unblended SiO lines have intensity 2. The visibility of the lines varies with the contrast in the spectrum, the stray light level, and with the presence or absence of strong competing lines, especially in the presence of broad and winged features. This accounts for the fragmentary appearance of the branches. Solar temperatures of 4000-5000K, which prevail in the solar atmosphere where SiO would be present, would require the rotational lines to peak in intensity at quantum number $N = 40$. The observations are consistent with this behavior.

A summary of the values of N for the lines identified in the three branches of the SiO bands is as follows:

SiO $A^1\Pi - X^1\Sigma^+$
Observed Rotational Quantum Numbers (N)

Band	P Branch	Q Branch	R Branch
0-1	absent	45-58	24-37, 49-65
1-0	31-38	16-47	24-50
2-0	absent	72-92	70-89

The (0-0) band should occur between 2345\AA and 2388\AA , but laboratory observations are lacking. The wavelengths in this interval have been calculated from the constants of the $X^1\Sigma^+$ state and the energy levels of the $A^1\Pi$ state determined from the (0-1) band, as given by A. Lagerqvist and U. Uhler.³¹ The evidence for the (0-0) band from these data was inconclusive; hence no lines from the (0-0) band are included in the ledger.

Although some lines in the various branches studied are absent and numerous lines are masked, enough are present or accounted for to confirm the presence of SiO.

The counts of identified lines of SiO are given below:

SiO $A^1\Pi - X^1\Sigma^+$

Band	Unblended	Blended	Total
0-1	9	13	22
1-0	19	12	31
2-0	13	4	17
Total	41	29	70

NH: The presence of NH in the solar spectrum is well established in the 1966 Solar Monograph.⁴² The (0-0) and (1-1) bands of the A³Π_u – X³Σ_g⁻ transition are red-degraded and have short wavelength limits at 3280Å and 3307Å, respectively. They are represented in this Monograph by 265 lines, 159 of which are unblended.

The (1-0) band is expected near 3050Å. This wavelength is at the extreme end of the present compilation, and overlaps a poorly observed region of the Rowland Table where the solar observations are discontinuous and fragmentary. Therefore, no identifications have been made, although this band may well be present. Laboratory observations by R. N. Dixon⁹ indicate that the (1-0) band is of strength comparable to the (0-0) and (1-1) bands. Further laboratory observations of the (1-0) band are needed.

Interpretation of Winged Lines

In the course of the early work on the Revision of Rowland's Preliminary Table of Solar Spectrum Wavelengths, (St. John et al. 1928) a study was made of the winged lines in the solar spectrum, 3000Å to 9000Å (Moore and Russell 1926). The strong, winged lines and those lines which were conspicuously hazy were selected by examining the Rowland and Mount Wilson photographs of the solar spectrum. These selected lines, totaling 138 were "subdivided into four groups according to the degree of widening"; group 1 contained the least widened lines and group 4 included only the H and K lines of Ca II. Eleven elements were represented: Fe, Mg, Ca, Ni, H, Ti, Na, Al, Si, Cr, and Sr.

By listing the widened lines of each spectrum in multiplet form it was shown that all originated in low energy levels, those from the lowest levels being the most widened. Strong members of multiplets were more widened than the weaker ones. The order of the elements listed above is roughly that of decreasing "total widening."

The study of the winged lines can now be extended to 2100Å from the data in Table I. Allowance must be made, however, for the fact that for $\lambda > 3000\text{\AA}$ the lines were selected from prints, while in the present work, the selection was made from photometric tracings. The earlier work has been extended by the same method of analysis. The lines in Table I have been divided into five groups according to the degree of widening, where Group 1 represents the least widened and Group 5 only the Mg lines. The distribution by groups is as follows:

Group	1	2	3	4	5
Width (Å)	0.3-0.5	0.6-0.9	1.0-1.9	2.0-5.0	>5.0

The winged lines are listed by spectra and in multiplet form in Table 5. The multiplets are taken from the Ultraviolet Multiplet Table except for one line of Fe I, 2983Å, which is from the Princeton Multiplet Table of 1945 as indicated by placing the multiplet number in brackets. These references are "UV" and "MT" respectively, in the solar ledger. The wavelengths quoted in the Table are those given in the Ledger. In some cases they differ from those in the Multiplet Tables because later reference material was used. The last column gives the widths grouped as described above. As was noted in the 1926 paper, the lines having the lowest excitation potentials are the most widened, in general, and the leading members of multiplets are widened more than the weaker ones.

Table 6 is a summary of the estimates of widening of winged lines in the echelle spectrum. A total of 76 unblended lines is included. The number of lines of each spectrum in Table I is tabulated for each width-group. Most of the lines are due to Fe and the strongest are produced by Mg. This table is essentially an extension of Table II in the 1926 paper, where it is stated that "The main cause of widening is shown to be almost entirely the abundance in the solar atmosphere of atoms which are in a condition to absorb the line in question." The extension of the range of the solar spectrum to 2100Å provides a more balanced comparison of widening and abundance. For example, the ultimate lines of Si I can now be included, whereas only one faint line (EP = 1.90 eV) was accessible at $\lambda > 3000\text{\AA}$. Mn II is also added. The earlier conclusions are well-confirmed in the present work.

Counts of Lines in the Ledger

The total number of lines recorded in the ledger is 6150. Of these, 3820 (62%) have been assigned a single identification, and 1100 (18%) are judged to be blends of two or more lines. In spite of careful literature search, some 20% or 1230 lines still remain unidentified. The strongest unidentified lines are listed in Table 7, which includes all unidentified lines having a solar intensity 4 or greater, totaling 150. These lines, in particular, are a challenge to those who continue work on the interpretation of XUV solar spectra.

PART IV

OTHER SOLAR OBSERVATIONS

High-resolution solar spectra in wavelength ranges that overlap or lie within the range of the present ledger have been obtained by several other groups. In the analysis of the echelle spectra no use was made of these later spectra, other than the occasional examination of an uncertain feature, or the search for a line expected but not found. Thus, the present solar line list is independent of results obtained by others. Similarly, the identifications are independent of identifications proposed by others; they depend only on the results from original laboratory spectroscopic work and the multiplet tables quoted as UV and MT.

The user of this ledger is encouraged, however, to make comparison with the results obtained by others. To facilitate comparison, a listing of relevant publications together with brief comments is presented in this part.

The Range Accessible from the Ground

A revision of the ultraviolet spectrum in the range 3650Å to 3000Å has been published by Mohler and Mitchell (1969). This was based on new tracings of the solar spectrum obtained with the McMath-Hulbert vacuum spectrograph in Michigan, and also with a similar instrument operated at the Mt. Wilson Observatory. Intercomparison with the Second Revision of Rowland's Table (Moore, Minnaert, Houtgast 1966) resulted in the reporting of several hundred new lines and proposed identifications.

The most extensive revision of the solar spectrum has been carried out by Pierce and Breckenridge (1973) with the McMath solar telescope at the Kitt Peak National Observatory (KPNO). In the range 2975Å to 3069Å the total number of lines listed is approximately the same as in the echelle ledger. Between 2918.82Å, the limit of the spectrum recorded by the KPNO, and 2975Å, the present echelle ledger contains about half again more lines. The wavelength accuracy of the KPNO results is exceedingly high, owing to the availability of a large number of photographic spectra, and the fact that standard spectra from a thorium hollow-cathode lamp were exposed on many of the plates just above and below the solar spectrum.

The Harvard-Smithsonian Atlas 2252Å to 3196 Å

On May 15, 1974 the Harvard-Smithsonian Center for Astrophysics flew an Aerobee rocket carrying a Fastie-Ebert photoelectric scanning spectrophotometer having a spectral resolution of 0.028Å. The results are presented in an Atlas (Kohl et al. 1978). Curves of intensity distribution are given for the center of the solar disc, and also for a region near the limb ($\mu = 0.23 \pm 0.04$).

From the point of view of spectral resolution the NRL and Harvard-Smithsonian curves are much alike, as should be, since the FWHM of the respective instrumental profiles was nearly the same. Likewise, each Atlas has regions where the data suffer from excessive noise, photographic and photoelectric. The intensity information in the Harvard-Smithsonian is superior, owing to the use of photoelectric recording, and because the stray-light level associated with the holographic grating and photoelectric detection was low.

The Hawaii Atlas — 2678Å to 2931Å

On June 19, 1974, only a month after the Harvard-Smithsonian flight, an echelle spectrograph with photographic recording was flown by Allen, McAllister, and Jefferies (1978) of the University of Hawaii. Culminating a development commenced in 1958 by McAllister and Rense at the University of Colorado, this instrument made use of an echelle grating crossed with a plane grating ruled with 1200 grooves per mm. Owing to the availability of a greatly improved echelle grating of 79 grooves per mm, a spectral resolution of the order of 0.02Å was achieved. Long-wavelength stray light was suppressed by the use of "solar blind" reflecting coatings (Hass and Tousey, 1959; Austin, 1969). Wavelengths were determined by reference to 350 lines, selected with the aid of the NRL Atlas and Preliminary Ledger. Rather than rely on photographic photometry for deriving values of the intensity, the curves were normalized in 5-Å intervals to the Harvard-Smithsonian Atlas. Over the range that it covers, the Hawaii Atlas is definitive. No line list has been published.

The Interferometer Spectrograph — 2756Å to 2831Å

A spectrograph that combined an echelle grating and a Fabry-Perot interferometer in crossed dispersion was developed jointly by the Culham Laboratory and the Queen's University of Belfast. (Bradley 1968; Bates et al. 1969, 1971). The spectral range covered on the flight of December 1968 was 2765Å to 2822Å, with a spectral resolution of 0.03Å. Improvements made in the instrument led to the attainment of 0.016Å-resolution over the interval 2756Å to 2831Å on November 27, 1969. A line list with identifications was published for the first spectra by Greve, McKeith and McKeith (1973) and another by Greve and McKeith (1974) for the second spectra. Identifications made in the latter were updated by Greve and McKeith (1977) from a comparison with the Harvard-Smithsonian Atlas.

In the first publication the solar line list was compared with the NRL Preliminary List, then available as a private communication. Although the spectral resolution of both instruments was about 0.03Å, more lines were listed than were found by NRL and there were many differences. Some of the differences can be attributed to the use of the NRL Ledger that was preliminary and from which some 10% of the solar lines in this range were discarded when preparing the Final Ledger. However, this is not a sufficient explanation because the line list from the second flight of the interferometric instrument contains only about 15% more lines than are present in the first list for the same spectral range, even though the spectral resolution was improved by a factor of two. Furthermore, the two interferometric lists are not in as close agreement as might be expected, especially for lines that are broad or weak. A detailed comparison with the Final Ledger has not been attempted. The agreement is believed satisfactory for the stronger lines, but not so for those that are weak.

Short Wavelength Echelle Spectra

An echelle spectrograph with all-reflecting optics that covered a spectral range of approximately 1000Å was designed and constructed by the Culham Laboratory group (Boland, Jones and Engstrom 1971a). Both this instrument and the NRL spectrograph used replicas of the same echelle master grating. The all-reflecting design made it possible to suppress stray light of longer

wavelengths by the use of selectively reflecting coatings and therefore to reach a shorter wavelength limit. From the flight of April 22, 1969 the spectra spanned the interval 2206.270Å to 2019.273Å with a resolution of 0.03Å, the same as for the NRL spectra. Improvements made in the reflecting coatings and thermal stability made it possible on the flight of March 20, 1973 to reach 1400Å and to secure a resolution of 0.025Å. (Boland et al. 1975)

A line list with identifications and analyses was published for the 1969 spectra by Boland et al. (1971b). In general there is excellent agreement with the present Ledger. The list extends about 85Å to shorter wavelengths and contains more lines as the end of the NRL coverage at 2095Å is approached. A revision of the list from the 1969 spectra, taking into account the spectra obtained in 1973, has not come to our attention.

Identifications Made by Others

The line identifications of Greve, McKeith and McKeith (1973) and of Greve and McKeith (1977) differ from those in the present ledger because of the inclusion of all lines from the laboratory literature that were in wavelength agreement with the particular solar feature to within the resolution-element of the spectrograph. In the NRL ledger, many such lines were excluded after consideration of the lack of importance of their contributions to the solar features, in order to identify the solar lines as positively as possible.

The line identifications of Boland et al., (1971b) were based mainly on the ultraviolet multiplet tables of Moore (UV), and the tables of Junkes, Salpeter and Milazzo (1965). They are consistent, in general, with those in the present ledger.

The line identifications included in the Harvard-Smithsonian Atlas were made by a procedure quite unlike that used in the present work. The identifications are based mainly on the exhaustive compilations of atomic *gf*-values published by Kurucz and Peytremann (1975) and are presented in the form of a synthetic spectrum. A recent extension of the spectral synthesis work by Kurucz and Avrett (1981) includes contributions of several molecular species.

As a final check on the major remaining unidentified lines in the present work, the 1975 compilation of *gf*-values was searched by C. M. Brown for coincidences. The only coincidences that were considered significant were found in Fe II.

PART V

ACKNOWLEDGMENTS

Completion of this publication brings to an end a project which commenced twenty years ago. In the preparation of this final ledger, the work was divided as follows: Selection of the solar lines that appeared to be real features, estimation of their visual intensities, and the final determination of wavelengths were carried out by R. Tousey, who has had the overall responsibility for the program since its inception. In close association since the very beginning has been C. E. Moore. Identification of the solar lines and the decisions as to contributors, blending, and masking were her responsibility. C. M. Brown supervised the work on molecular lines and surveyed the literature. The section on Molecular Spectra was provided by him. In addition, he has taken charge of the computer programming and the preparation of the tables for publication.

To thank individually all who contributed to this extended project is hardly practicable. We are most grate-

ful to all who have participated. Contributions best described as invaluable were made by several colleagues formerly at NRL. J. D. Purcell developed the instrumentation and prepared the spectra in a form suitable for study. L. E. Giddings prepared the first line list and P. A. Simmons provided the identifications in the preliminary list. E. Milone contributed in many ways during more than a decade of part-time association. The Atlas was the responsibility of S. G. Tilford.

We are indebted to many individuals who have provided spectroscopic data and assistance in general. In particular, we thank B. Edlén and S. Johansson of Lund, L. Iglesias of Madrid, and W. C. Martin and R. Zalubas of the National Bureau of Standards.

We appreciate the helpful advice of T. Chewning and L. J. Palumbo on computerizing the printing of this Report, and the assistance given by the NRL Computerized Technical Composition Section.
